ABSTRACT A stock loan is a contract whereby a stockholder uses shares as collateral to borrow money from a bank or financial institution. In Xia and Zhou (2007, Stock loans, Mathematical Finance, 17(2), pp. 307–317), this contract is modelled as a perpetual American option with a time-varying strike and analysed in detail within a risk-neutral framework. In this paper, we extend the valuation of such loans to an incomplete market setting, which takes into account the natural trading restrictions faced by the client. When the maturity of the loan is infinite, we use a time-homogeneous utility maximization problem to obtain an exact formula for the value of the loan fee to be charged by the bank. For loans of finite maturity, we characterize the fee using variational inequality techniques. In both cases, we show analytically how the fee varies with the model parameters and illustrate the results numerically.

KEY WORDS: Stock loans, indifference pricing, illiquid assets, incomplete markets

1. Introduction

A stock loan is a contract between two parties: the lender, usually a bank or other financial institution providing a loan, and the borrower, represented by a client who owns one share of a stock used as collateral for the loan. Several reasons might motivate the client to get into such a deal. For example, he might not want to sell his stock or even face selling restrictions, while at the same time being in need of available funds to attend to another financial operation.

Our main task consists of determining the fair values of the parameters of the loan, particularly the value of the fee that the bank charges for the service along with the interest rate to be charged over the amount borrowed, taking into account the stock price at the moment of taking the loan. In addition, we take into account the fact that the bank typically collects any dividends paid by the stock for the duration of the loan. Finally, whereas the client can recover the stock at any time by paying the loan principal plus interest, he is not obliged to do so, even if the stock price falls down, and this optionality also needs to be accounted in the valuation of the loan.

In Xia and Zhou (2007), a stock loan is modelled as a perpetual American option with a time-varying strike and analysed in detail using probabilistic methods within
the Black–Scholes framework. Assuming that the risk-neutral dynamics of the stock follows a geometric Brownian motion, they obtained explicit formulas for the bank’s fee in terms of the amount lent and the stock price at the moment of signing the loan. Implicit in their use of the risk-neutral paradigm is the assumption that the option can be replicated by trading in the underlying stock and the money market. Whereas this is certainly plausible from the bank’s point of view, we argue that neither type of trade is readily available for the client, who presumably does not have unrestricted access to the money market (hence the need to post collateral in the form of a stock) nor can freely trade in the stock (otherwise he would simply sell the stock instead of take the loan). Moreover, while risk-neutral valuation yields the fair price at which the option itself can be traded in the market without introducing arbitrage opportunities, a stock loan typically cannot be sold or bought in a secondary market once it is initiated. In other words, the client does not operate in the frictionless market that is assumed by the Black–Scholes framework.

Accordingly, we treat a stock loan as an option in an incomplete market. We assume that the client cannot trade directly in the underlying stock, but is allowed to trade in a portfolio of assets that is imperfectly correlated to the stock. In this way, since the client cannot perfectly hedge the embedded optionality, he faces some non-diversifiable risk for the duration of the loan. We assume that the client is a risk averse economic agent and model his preferences by an exponential utility function. We then use utility indifference arguments to value the stock loan from the point of view of the client both for infinite maturity, where semi-explicit formulas are still available, and for finite maturity, where numerical computations are needed. Finally, we assume that the bank is well diversified and relate the fee charged by the bank with the hedging cost for a barrier-type option reflecting the exercise behaviour of the client.

Although we present the analysis using a financial asset as the collateral, it is clear that the same results can be applied to loans against other types of assets, such as real estate or inventories, provided their value is observable and follows a dynamics that can be modelled according to (1).

2. Model Set-Up

We consider a market consisting of two correlated assets $S$ and $V$ with ‘discounted’ prices given by

$$
\begin{align*}
    dS_t &= (\mu_1 - r)S_t dt + \sigma_1 S_t dW_t^1, \\
    dV_t &= (\mu_2 - r)V_t dt + \sigma_2 V_t \left( \rho dW_t^1 + \sqrt{1 - \rho^2} dW_t^2 \right),
\end{align*}
$$

for $t_0 \leq t \leq T \leq \infty$, where $W = (W^1, W^2)$ is a standard two-dimensional Brownian motion. We suppose further that the client can trade dynamically by holding $H_t$ units of the asset $S_t$ and investing the remaining of his wealth in a bank account with normalized value $B_t = e^{(t-t_0)}$ for a constant interest rate $r$. It follows that the discounted value of the corresponding self-financing portfolio satisfies

$$
\begin{align*}
    dX_t^\pi &= \pi_t (\mu_1 - r) dt + \pi_t \sigma_1 dW_t^1, \\
    t_0 \leq t \leq T,
\end{align*}
$$

where $\pi_t = H_t S_t$. 

At a given time $t_0$, the client borrows an amount $L$ from a bank leaving the asset with value $V_{t_0}$ as a collateral. We assume that the bank collects the dividends paid by the underlying asset $V$ at a rate $\delta$ for the duration of the loan. In addition, the bank charges the client a fee $c$ and stipulates an interest rate $\alpha$ to be charged on the loan amount $L$, so that the client can redeem the asset with value $e^{(r-\delta)(t-t_0)}V_t$ at time $t_0 \leq t \leq T$ by paying an amount $e^{\alpha(t-t_0)}L$. At the maturity time $T$, we assume that the client needs to decide between repaying the loan or forfeiting the underlying asset indefinitely.

In other words, at the beginning of the loan, the client gives the bank an asset worth $V_{t_0}$ and receives a net amount $(L - c)$ plus the option to buy back an asset with market price $e^{\alpha(t-t_0)}V_t$ for an amount $e^{\alpha(t-t_0)}L$. Denoting the cost of this option for the bank by $C_{t_0}$, the loan parameters are related by

$$c = L + C_{t_0} - V_{t_0}. \quad (3)$$

### 3. Infinite Maturity

Let us first assume that $T = \infty$ and $\alpha = r$. Given an exponential utility $U(x) = -e^{-\gamma x}$, we consider a client trying to maximize the expected utility of discounted wealth. We assume that, upon repaying the loan at time $\tau$, the borrower adds the discounted payoff $(V_\tau - L)$ to his discounted wealth $X_{\pi \tau}$ and continues to invest optimally. Accordingly, having taken the loan at time $t_0$, the borrower needs to solve the following optimization problem:

$$G(x, v) = \sup_{(\tau, \pi) \in \mathcal{A}} \mathbb{E} \left[ -e^{\frac{\mu_1 - \alpha^2}{2\tau}} e^{-\gamma (X_{\pi \tau} + (V_\tau - L)\tau)} | X_{t_0} = x, V_{t_0} = v \right]. \quad (4)$$

Here, $\mathcal{A}$ is a set of admissible pairs $(\tau, \pi)$, where $\tau \in [0, \infty]$ is a stopping time and $\pi$ is a portfolio process. Observe that the factor $e^{\frac{\mu_1 - \alpha^2}{2\tau}}$ leads to a horizon-unbiased optimization problem (see appendix 1 of Henderson (2007) for details), while the choice $\alpha = r$ removes the dependence on time from the factor $e^{(\alpha - \delta)(t-t_0)}$ at the repayment date. Combined with the infinite maturity assumption, this allows us to deduce that the borrower should decide to pay back the loan at the first time that $V$ reaches a stationary threshold $V^*$, that is,

$$\tau^* = \inf\{s \geq t_0 : V_s = V^*\}. \quad (5)$$

We follow Hodges and Neuberger (1989) and define the indifference value for the option to pay back the loan as the amount $p(v)$ satisfying

$$G(x, 0) = G(x - p(v), v). \quad (6)$$

The following proposition summarizes the results in Henderson (2007) regarding the value function $G(x, v)$, the threshold $V^*$ and the indifference value $p(v)$.
Proposition 3.1. The function $G(x,v)$ solves the following non-linear Hamilton–Jacobi–Bellman (HJB) equation:

$$
\frac{(\mu_1 - r)^2}{2\sigma_1^2} G + \frac{\sigma_2^2 v^2}{2} G_{vv} + (\mu_2 - r)v G_v - \frac{(\rho \sigma_1 \sigma_2 v G_v + (\mu_1 - r)G_x)^2}{\sigma_1^2 G_{xx}} = 0
$$

subject to the following boundary, value matching and smooth pasting conditions:

$$
G(x,0) = -e^{-\gamma x}
$$

$$
G(x,V^*) = -e^{-\gamma (x + V^* - L)}
$$

$$
G_v(x,V^*) = \gamma e^{-\gamma (x + V^* - L)}.
$$

Let $\beta = 1 - \frac{2}{\sigma_1} \left( \frac{\mu_2 - r}{\sigma_2} - \rho \frac{\mu_1 - r}{\sigma_1} \right)$. If $\beta \geq 0$, the threshold $V^* \geq L$ is the unique solution to

$$
V^* - L = \frac{1}{\gamma (1 - \rho^2)} \log \left[ 1 + \frac{\gamma (1 - \rho^2) V^*}{\beta} \right]
$$

and the solution to (7) and associated conditions is given by

$$
G(x,v) = \begin{cases} 
- e^{-\gamma x} F(v) \frac{1}{1 - \rho^2}, & \text{if } v < V^* \\
- e^{\gamma x} e^{-\gamma (v - L)}, & \text{if } v \geq V^*, 
\end{cases}
$$

where

$$
F(v) = 1 - (1 - e^{-\gamma (V^* - L)(1 - \rho^2)}) \left( \frac{v}{V^*} \right)^\beta.
$$

In this case, the indifference value $p^{(\rho,\gamma)}$ is given by

$$
p(v) = \begin{cases} 
- \frac{1}{\gamma (1 - \rho^2)} \log F(v), & \text{if } v < V^* \\
(v - L), & \text{if } v \geq V^*, 
\end{cases}
$$

Moreover, the optimal hedging strategy for the client before exercising the option to repay is

$$
\pi^*(v) = \frac{\mu_1 - r}{\gamma \sigma_1^2} - \frac{\rho \sigma_2 v p_v(v)}{\sigma_1}.
$$

Alternatively, if $\beta \leq 0$, then the smooth pasting fails and there is no solution to (7) and associated conditions. In this case, $V^* = \infty$ and the option to repay the loan is never exercised.

Let us assume from now on that $S$ is the discounted price of the market portfolio, so that the equilibrium rate of return $\overline{\mu}_2$ on the asset $V$ satisfies the capital asset pricing model (CAPM) condition:
The dividend rate paid by $V$ is then $\delta = \mu_2 - \mu_1$, and we have that

$$\beta = 1 - \frac{2}{\sigma_2} \left( \frac{\mu_2 - r}{\sigma_2} - \rho \frac{\mu_1 - r}{\sigma_1} \right) = 1 + \frac{2\delta}{\sigma_2} > 0.$$ 

(14)

Because the bank is well-diversified and can hedge in the financial market by directly trading the asset $V$, the cost $C_0 = C(V_0)$ of granting the repayment option is given by the complete market price of a perpetual barrier-type call option on $e^{(r-t_0)V_t}$, with strike $e^{\alpha(t-t_0)L}$ exercised at the borrower’s optimal exercise boundary obtained in Proposition 3.1. In other words, denoting by $Q$ the unique risk-neutral measure for the complete market consisting of $S$ and $V$, we have the following result.

**Proposition 3.2.** Assuming that the borrower exercises the repayment option optimally according to Proposition 3.1, the cost of this option for the bank is given by

$$C(v) = \begin{cases} \left( V^* - L \right) E^Q \left( I_{[\tau^* < \infty]} \right), & \text{if } v < V^* \\ v - L, & \text{if } v \geq V^* \end{cases},$$

where $W^Q$ is a Brownian motion. Therefore, $E^Q \left( I_{[\tau^* < \infty]} \right)$ corresponds to the risk-neutral probability that the geometric Brownian motion $V_t$ started at $V_{t_0} = v$ will cross the barrier $V^*$ in a finite time. The result then follows from standard Laplace transform techniques.

We can now use (3) and (15) to establish that

$$c = L + C_0 - V_{t_0} = \begin{cases} L + (V^* - L) \left( \frac{v}{V^*} \right)^\beta - V_{t_0}, & \text{if } V_{t_0} < V^* \\ 0, & \text{if } V_{t_0} \geq V^* \end{cases}.$$ 

(17)

As shown in proposition 3.5 of Henderson (2007), one can find by direct differentiation of expressions (8) and (11) that both the threshold $V^*$ and the indifference value $p(v)$ are increasing in $\rho^2$. In other words, all things being equal, a higher degree of market incompleteness, expressed as a smaller absolute value for the correlation between the stock and the market portfolio, lead the client to exercise the option to repay the loan earlier than in the complete market case, resulting in a smaller indifference value for the option. Similarly, both $V^*$ and $p(v)$ are decreasing in $\gamma$, meaning that a higher degree of risk aversion has a similar effect in decreasing the value of the option to repay the loan. These properties carry over to the loan fee obtained in expression (17), as we establish in the next proposition.
Proposition 3.3. The loan fee:

1. decreases as the risk aversion $\gamma$ increases,
2. decreases as the dividend rate $\delta$ increases and
3. increases as $\rho^2$ increases.

Moreover, its limiting values as either $\rho^2 \to 1$ or $\gamma \to 0$ coincide and are given by

$$c = \begin{cases} L + \left( \tilde{V} - L \right) \left( \frac{V_t}{\beta} \right) \beta - V_t, & \text{if } V_t < V^* \\ 0, & \text{if } V_t \geq V^* \end{cases}$$

where

$$\tilde{V} = \frac{\beta}{\beta - 1} L = \left( 1 + \frac{\alpha^2}{2\gamma} \right) L.$$

Proof. The first part of the proposition follows by explicit differentiation of expressions (8), (14) and (17). For the second part, observe that it follows from our equilibrium condition (13) that both limiting thresholds in proposition 3.5 of Henderson (2007) are given by $\tilde{V} = \frac{L}{\beta} L$. Substituting expression (14) for $\beta$ then completes the proof.

We conclude this section by observing that the limiting threshold $\tilde{V}$ corresponds to the complete market threshold $a_0$ found in Xia and Zhou (2007) using risk-neutral valuation arguments. Consequently, provided $\alpha = r$, the complete market, risk-neutral setting can be recovered as a special case of our results.

3.1 Suboptimal Exercise by the Client

We obtained the fee in (17) under the assumption that the borrower exercises the repayment option optimally. Moreover, we implicitly assume that the bank knows that the client has an exponential utility with risk-aversion parameter $\gamma$. It is therefore interesting to investigate the risks faced by the bank when these assumptions are violated.

To address the first issue, suppose that the client exercises the repayment option when the stock price crosses an arbitrary threshold $B$. The cost for the bank associated with this exercise strategy is therefore given by

$$C_B(v) = \begin{cases} (B - L) \left( \frac{v}{\beta} \right)^\beta, & \text{if } v < B \\ v - L, & \text{if } v \geq B \end{cases}$$

The highest cost for the bank corresponds to a threshold $B$ that maximizes this expression for each fixed $v$. Following the well-known approach described, for example, in chapter 8 of Shreve (2004), we define

$$g(B) = \frac{B - L}{B^\beta}$$

and seek for the value of $B$ that maximizes this function over $B \geq 0$. Since $\beta \geq 1$, we see that
\[ \lim_{B \to 0^+} g(B) = -\infty \]
\[ \lim_{B \to \infty} g(B) = 0. \]

Moreover,
\[ g'(B) = \frac{B^\beta - (B - L)\beta B^{\beta-1}}{B^\beta} \]

and setting this equal to zero gives
\[ B^* = \frac{\beta}{\beta - 1}L = \bar{V}. \] (20)

This is shown in Figure 1. We see that the highest cost for the bank occurs when the client exercises the repayment option using the threshold \( B^* = \bar{V} \), which according to Proposition 3.3 corresponds to either a complete market (\( \rho^2 = 1 \)) or a risk-neutral client (\( \gamma = 0 \)). We also see from Figure 1 that suboptimal exercise by the client can have both a positive or a negative impact on a bank that uses Proposition 3.2 to compute the cost associated with the loan. This is because exercise either before the optimal threshold \( V^* \) or after the threshold \( V_2 \) (marked in the figure) leads to a lower cost, whereas exercise between \( V^* \) and \( V_2 \) leads to a higher cost (with a maximum at \( B^* = \bar{V} \)) than previously estimated by the bank.

Regarding the choice of the parameter \( \gamma \), the bank can either infer it indirectly from the client’s investment decisions (using the methods described in the vast literature started with the seminal work of Cohn et al. (1975)) or try to assess it directly by surveying the client’s attitudes towards various specified lotteries (see, e.g., Kagel and Roth, 1995). Whatever the method used by the bank will result in a range of estimates of \( \gamma \), which should then be used in conjunction with the statistical estimates for the other model parameters and a sensitivity analysis of the type provided in Section 5.1 to help it determine the risks associated with the loan.

4. Finite Maturity

4.1 The Free Boundary Problem

Consider \( T = \infty \) and define the value function (see Merton, 1969)
\[ M(t, x) = \sup_{\pi \in \mathcal{A}[t, \tau]} \mathbb{E} \left[ -e^{-r\tau} X^\tau_t \mid X^\pi_t = x \right] = -e^{-r\tau} e^{-\frac{(\omega_0 - \bar{x})^2}{2\sigma^2} (T-t)}, \] (21)

for \( t_0 \leq t \leq T \), where \( X^\pi_t \) follows the dynamics (2) and \( \mathcal{A}[t, T] \) is the set of admissible investment policies on the interval \([t, T]\), which we take to be progressively measurable processes satisfying the integrability condition:
\[ \mathbb{E} \left[ \int_t^T \pi^2_s \, ds \right] < \infty. \]
As before, let the repayment time be a stopping time $\tau$ and assume that the borrower will add the discounted payoff $(V_\tau - e^{(\alpha-r)(t-t_0)} L)^+$ to his discounted wealth $X_\tau^{\pi}$ at time $\tau$ and then invest optimally until time $T$. Accordingly, having taken the stock loan at time $t_0$, the borrower considers the following optimization problem:

$$u(t_0, x, v) = \sup_{\tau \in T[t_0, T]} \sup_{\pi \in \mathcal{A}[\tau]} \mathbb{E} \left[ M \left( \tau, X_\tau^{\pi} + \left( V_\tau - e^{(\alpha-r)(t-t_0)} L \right)^+ \right) \mid X_{t_0} = x, V_{t_0} = v \right] ,$$

where $T[t_0, T]$ denotes the set of stopping times in the interval $[t_0, T]$. The indifference value for the repayment option is then given by the amount $p$ satisfying

$$M(t_0, x) = u(t_0, x - p, v).$$

(23)

It follows from the dynamic programming principle that the value function $u$ solves the free boundary problem:

$$\begin{cases}
\frac{\partial u}{\partial t} + \sup_{\pi} \mathcal{L}^\pi u & \leq 0, \\
u(t, x, v) & = \Lambda(t, x, v), \\
\left( \frac{\partial u}{\partial t} + \sup_{\pi} \mathcal{L}^\pi u \right) \cdot (u - \Lambda) & = 0,
\end{cases}$$

for $(t, x, v) \in [t_0, T) \times \mathbb{R} \times (0, \infty)$, where
\[ \mathcal{L}^\pi = (\mu_2 - r)\frac{\partial}{\partial v} + \frac{\sigma_2^2 v^2}{2} \frac{\partial^2}{\partial v^2} + \pi (\mu_1 - r) \frac{\partial}{\partial x} + \rho \pi \sigma_2 v \frac{\partial^2}{\partial x \partial v} + \frac{\pi^2 \sigma_1^2}{2} \frac{\partial^2}{\partial x^2} \]

is the infinitesimal generator of \((X^\pi, V)\) and

\[ \Lambda(t, x, v) = M(t, x + (v - e^{(\mu - r)(t-t_0)})L) \]

is the utility obtained from exercising the repayment option at time \(t\). The boundary conditions for Problem (24) are

\[ u(T, x, v) = -e^{-\gamma(1 - \rho^2)\pi (v - e^{(\alpha - r)(T-t_0)})L} \]

\[ u(t, x, 0) = -e^{-\gamma} e^{-\frac{\mu_1 - r}{\sigma_1} (T-t)} \].

Using the factorization

\[ u(t, x, v) = -e^{-\gamma} F(t, v) e^{\frac{1}{\rho \pi}} \],

we find that the corresponding free boundary problem for \(F\) becomes

\[ \begin{cases} \frac{\partial F}{\partial t} + \mathcal{L}^0 F & \geq 0, \\ F(t, v) & \leq \kappa(t, v), \\ \left(\frac{\partial F}{\partial t} + \mathcal{L}^0 F\right) \cdot (F - \kappa) & = 0, \end{cases} \] (27)

for \((t, v) \in [t_0, T) \times (0, \infty)\), where

\[ \mathcal{L}^0 = \left[ \mu_2 - r - \rho \frac{\mu_1 - r}{\sigma_1} \frac{\partial}{\partial v} + \frac{\sigma_2^2 v^2}{2} \frac{\partial^2}{\partial v^2} \right] \] (28)

and

\[ \kappa(t, v) = e^{-\gamma(1 - \rho^2)\pi (v - e^{(\alpha - r)(T-t_0)})L} \].

The boundary conditions for Problem (27) are

\[ F(T, v) = e^{-\gamma(1 - \rho^2)\pi (v - e^{(\alpha - r)(T-t_0)})L} \]

\[ F(t, 0) = 1. \] (30)

Since Problem (27) is independent of \(X\) and \(S\), we define the borrower’s optimal exercise boundary as the function

\[ V^*(t) = \inf \{ v \geq 0 : F(t, v) = \kappa(t, v) \} \] (31)

and the optimal repayment time as
\begin{equation}
\tau^* = \inf \{ t_0 \leq t \leq T : V_t = V^*(t) \}.
\end{equation}

It follows from the definition (23) and the factorization (26) that the indifference value for the repayment option is given by

\begin{equation}
p(t, v) = -\frac{1}{\gamma(1 - \rho^2)} \log F(t, v).
\end{equation}

Therefore, the original free boundary problem can be rewritten in terms of the indifference value as

\begin{equation}
\begin{aligned}
\frac{\partial p}{\partial t} + \mathcal{L}^0 p - \frac{1}{2} \gamma (1 - \rho^2) \sigma_2^2 v^2 \left( \frac{\partial p}{\partial v} \right)^2 & \leq 0, \\
p(t, v) & \geq (v - e^{(a - r)(t-t_0)} L)^+, \\
\left[ \frac{\partial p}{\partial t} + \mathcal{L}^0 p - \frac{1}{2} \gamma (1 - \rho^2) \sigma_2^2 v^2 \left( \frac{\partial p}{\partial v} \right)^2 \right] \cdot (p - (v - e^{(a - r)(t-t_0)} L)^+) & = 0,
\end{aligned}
\end{equation}

Similarly, the optimal exercise time \( \tau^* \) can be expressed in terms of \( p \) as follows:

\begin{equation}
\tau^* = \inf \{ t_0 \leq t \leq T : p(t, V_t) = (V_t - e^{(a - r)(t-t_0)} L)^+ \}
\end{equation}

Finally, the optimal trading strategy for client before exercising the option is

\begin{equation}
\pi^*(t, v) = \frac{\mu - r}{\gamma \sigma_1^2} - \frac{\rho \sigma_2 \sigma_p}{\sigma_1} \frac{\partial p}{\partial v}.
\end{equation}

Observe that the first term above corresponds to the classical Merton allocation in the absence of the option to repay the loan, whereas the second term is the excess hedge allocation, which can be seen as a generalized delta-hedge in an incomplete market setting.

Once we find the optimal exercise boundary \( V^*(t) \), say by solving problem (27) numerically, we can calculate the bank’s cost of granting the repayment option as the risk-neutral value of a barrier-type call option on \( e^{(t-t_0)} V_t \) with strike \( e^{(a - r)(t-t_0)} L \) and maturity \( T \) exercised at the barrier \( e^{(t-t_0)} V^*(t) \). In other words,
\[ C_0 = C(t_0, v) = E^Q \left[ e^{-r(t_0-h)} \left( e^{(r-h)h} V^* + e^{(r-h)H} L \right) \right] 1_{\tau^* < \infty} \mid V_{t_0} = v \]  
\[ = E^Q \left[ e^{-\tilde{r}(t_0-h)} \left( e^{(\tilde{r}-\alpha)h} V^* - L \right) \right] 1_{\tau^* < \infty} \mid V_{t_0} = v \]  
\[ = E^Q \left[ e^{-\tilde{r}(t_0-h)} \left( \tilde{V}^* - L \right) \right] 1_{\tau^* < \infty} \mid V_{t_0} = v \]  

where \( \tilde{r} = r - \alpha \) and \( \tilde{V}^* = e^{(\tilde{r}-\alpha)h} V^* \). Denoting \( \tilde{V}_i = e^{(\tilde{r}-\alpha)h} V_i \), it is trivial to see that \( \tau^* \) defined in (32) can be written as

\[ \tau^* = \inf \{ t_0 \leq t \leq T : V_i = V^* \} = \inf \{ t_0 \leq t \leq T : \tilde{V}_i = \tilde{V}^* \}. \]  

Therefore, since the risk-neutral dynamics for the process \( \tilde{V}_i \) is

\[ d\tilde{V}_i = (\tilde{r} - \delta) V_i dt + \sigma_2 V_i dW^Q_i, \]

we have that the function \( C(t, v) \) satisfies the Black–Scholes partial differential equation (PDE)

\[ \frac{\partial C}{\partial t} + (r - \alpha - \delta) v \frac{\partial C}{\partial v} + \frac{\sigma^2 v^2}{2} \frac{\partial^2 C}{\partial v^2} = (r - \alpha) C \]  

over the domain \( \mathcal{D} = \{ (t, v) : t_0 \leq t \leq T, 0 \leq v \leq V^* \} \), subject to the boundary conditions

\[ C(t, 0) = 0, \quad t_0 \leq t \leq T; \]

\[ C(t, \tilde{V}^*) = (\tilde{V}^* - L)^+ \mid \tilde{V}_t = \tilde{V}^*, \quad t_0 \leq t \leq T; \]

\[ C(T, v) = (v - L)^+, \quad 0 \leq v \leq \tilde{V}^*(T). \]

As before, once we calculate the cost \( C_0 \), the fee to be charged for the loan is given by (3). It is easy to see that the cost \( C_0 \), and consequently the fee \( c \), increases if the optimal exercise boundary \( V^* \) is shifted upwards and decreases otherwise.

### 4.2 Properties of the Loan Fee

In this section, we investigate how the loan fee to be charged by the bank depends on the underlying parameters. We will always assume that the interest rate \( r \), the expected return \( \mu_1 \) and the volatility \( \sigma_1 \) for the market portfolio \( S \), the loan interest rate \( \alpha \) and the loan amount \( L \) are fixed. On the other hand, we treat the risk aversion \( \gamma \), the dividend rate \( \delta \), the correlation \( \rho \) and the underlying asset volatility \( \sigma_2 \) as variable parameters. We then perform comparative statics, that is, we change each of these parameters while keeping the others constant and analyse the corresponding behaviour of the loan fee.
Observe that for each choice of values for $\delta$, $\sigma_2$ and $\rho$, the expected return $\mu_2$ is automatically determined by the assumption that the asset prices are in equilibrium. For simplicity, we continue to assume that $S$ is the discounted price of the market portfolio, so that the CAPM condition (13) holds and we have that

$$\mu_2 = \rho \frac{\mu_1 - r}{\sigma_1} \sigma_2 + r - \delta. \quad (44)$$

The behaviour of the loan fee with respect to the underlying parameters is established in the next proposition, which we prove using the same technique as in Leung and Sircar (2009), but adapted the problem at hand.

**Proposition 4.1.** The loan fee $c$:

1. decreases as the risk aversion $\gamma$ increases,
2. decreases as the dividend rate $\delta$ increases and
3. increases as $\rho^2$ increases.

**Proof.** Observe first that for fixed values of $L$, $\alpha$ and $r$, it follows from (35) that a smaller indifference value leads to a smaller optimal exercise time, which in turn implies a lower optimal exercise boundary and consequently a smaller loan fee. To establish how the indifference value changes with the underlying parameters, we use the comparison principle for the variational inequality

$$\min \left\{ -\frac{\partial p}{\partial t} - L^0 p + \frac{1}{2} \gamma (1 - \rho^2) \sigma_2^2 \left( \frac{\partial p}{\partial v} \right)^2 , p(t,v) - \left( v - e^{(a-r)(t-t_0)} L \right)^+ \right\} = 0,$$

which is known to be equivalent to (34).

For item (1), observe that the variational inequality (45) depends on $\gamma$ only through the nonlinear term

$$\frac{1}{2} \gamma (1 - \rho^2) \sigma_2^2 \left( \frac{\partial p}{\partial v} \right)^2.$$

Since this is increasing in $\gamma$, it follows that $p$ is decreasing in $\gamma$.

For item (2), observe first that $\frac{\partial p}{\partial \delta} \geq 0$, because $u(t_0, x, v)$ defined in (22) (and consequently $p(t, v)$) is an increasing function $v$. Next, recalling the definition of $L^0$ in (28), we see that the variational inequality (45) depends on $\delta$ through the term

$$- \left[ \mu_2 - r - \rho \frac{\mu_1 - r}{\sigma_1} \sigma_2 \right] \frac{\partial p}{\partial v} = \delta \frac{\partial p}{\partial v},$$

on account of (44). Since this is increasing in $\delta$, we have that $p$ is decreasing in $\delta$.

Similarly, for item (3), using (28) we see that the variational inequality (45) depends on $\rho$ through the term
By virtue of (44), we then see that the dependence on $\rho$ reduces to the nonlinear term (46). Therefore, the indifference price is a symmetric function of $\rho$ and increases as $\rho^2$ increases from 0 to 1.

Notice that the variational inequality (45) depends on $\sigma_2$ through the term

$$-\frac{\sigma_2^2 v^2}{2} \frac{\partial^2 p}{\partial v^2} + \frac{1}{2} \gamma (1 - \rho^2) \sigma_2^2 v^2 \left( \frac{\partial p}{\partial v} \right)^2.$$ (47)

Since this is not necessarily monotone in $\sigma_2$, we cannot expect the indifference value, and consequently the loan fee $c$, to be a monotone function of the underlying stock volatility.

Regarding the behaviour of the loan fee with respect to the maturity length of the loan, one intuitively expects that a longer maturity increases the optionality of the repayment and should contribute to higher fee. As establish in the next proposition, this is indeed the case, provided we can ignore the effects of interest rates.

**Proposition 4.2.** If $\alpha = r$, the loan fee is an increasing function of the maturity $T$.

**Proof.** The solution to problem (27) admits a probabilistic representation (see Oberman and Zariphopoulou, 2003) of the form

$$F(t, v) = \inf_{\tau \in [t, T]} E^0[k(\tau, V_\tau)|V_t = v],$$

where $E^0[\cdot]$ denotes the expectation operator under the ‘minimal martingale measure’ $Q^0$ defined by

$$\frac{dQ^0}{dP} = e^{-\mu_1 r - \frac{1}{2} \sigma_1^2 T}.$$ (48)

When $\alpha = r$, we can use the fact that $V_t$ is a time-homogeneous diffusion to obtain that

$$F(t, v) = \inf_{\tau \in [t, T]} E^0[e^{-\gamma (1 - \rho^2)(V_\tau - L)^+}|V_t = v] = \inf_{\tau \in \{t_0, T - t + t_0\}} E^0[e^{-\gamma (1 - \rho^2)(V_\tau - L)^+}|V_{t_0} = v].$$

For any $s \leq t$, we have that $T[t_0, T - t + t_0] \subset T[t_0, T - s + t_0]$, so $F(s, v) \leq F(t, v)$. Now, fix $v \geq 0$ and suppose that it is optimal to exercise at $(s, v)$, that is, $F(s, v) = k(s, v)$. Using the fact that $F$ is increasing in time (as we just established), we have that
Stock Loans in Incomplete Markets

\[ e^{-\gamma(1-\rho^2)(r-L)^+} = k(s,v) = F(s,v) \leq V(t,v) \leq k(t,v) = e^{-\gamma(1-\rho^2)(r-L)^+}, \]

so that \( F(t,v) = k(t,v) \), which implies that it is also optimal to exercise at \( (t,v) \). This means that, for each fixed \( T \), the optimal exercise boundary \( V^*(t) \) is a decreasing function of time, and consequently an increasing function of the time-to-maturity parameter \( (T-t) \). Therefore, as we modify the problem by increasing the maturity \( T \), the optimal exercise boundary shifts upwards, leading to a higher cost for the bank and a higher loan fee.

5. Numerical Results

5.1 Infinite Maturity

The only numerical step involved in this case consists of finding the value of the threshold \( V^* \) by solving the non-linear Equation (8) for given parameter values. We can then use expression (17) to find the loan fee \( c \). For comparison, we calculate the corresponding loan fee in a complete market scenario using the formulas found in Xia and Zhou (2007). Observe that we always need to use \( r = \alpha \) as explained in Section 3 in order to maintain time homogeneity.

We start by calculating the value of the loan fee \( c \) for a range of loan amounts \( L \) and four different sets of model parameters. The results are summarized in Table 1 and correspond to the following cases:

(1) Complete market with \( \sigma_2 = 0.15, \delta = 0, r = 0.05, \alpha = 0.05 \) and \( V_{t_0} = 100 \). This corresponds to case (a) of theorem 3.1 in Xia and Zhou (2007), that is, \( \delta = 0 \) and \( \alpha - r < \sigma_2^2/2 \). Because the stock pays no dividend and the excess interest rate on the loan is small, it follows that the option to repay the loan has the same value as the stock itself (i.e., \( C_{t_0} = V_{t_0} \)), which leads to \( c = L \). In other words, the bank has no incentive to provide the loan and charges a fee exactly equal to the loan amount. In effect, the client gives away the stock and receives a perpetual American option with an infinite exercise threshold.

(2) Incomplete market with \( \sigma_2 = 0.15, \delta = 0, r = 0.05, \alpha = 0.05, V_{t_0} = 100, \rho = 0.9 \) and \( \gamma = 0.01 \). This is the incomplete market analogue of the previous case. We see that incompleteness and risk aversion lead to a finite exercise threshold \( V^* \) even when the stock pays no dividend and the excess interest rate on the loan is

</table>
small. In other words, the option to repay the loan is exercised sooner, and consequently has a smaller value for the client, than in the complete market case. As a consequence, the bank has a smaller cost for providing the loan and can charge a reduced fee \( c < L \).

(3) Complete market with \( \sigma^2 = 0.15, \delta = 0.05, r = 0.05, \alpha = 0.05 \) and \( V_{t_0} = 100 \). This corresponds to case (b) of theorem 3.1 in Xia and Zhou (2007), since \( \delta \geq 0 \). To calculate \( c \), we first find the exercise threshold \( a_0 \) as in page 314 of Xia and Zhou (2007) for each value of \( L \). If \( a_0 \leq V_{t_0} = 100 \) (which happens for low enough \( L \)), then \( c = 0 \), meaning that the client receives \( L \) in exchange of \( V_{t_0} \) at no cost, and then immediately exercises the option to repay. In other words, there is no incentive for the client to seek the loan. On the other hand, if \( a_0 \geq V_{t_0} \), we calculate the fee \( c \) using the formula at the end of page 316 of Xia and Zhou (2007).

(4) Incomplete market with \( \sigma^2 = 0.15, \delta = 0.05, r = 0.05, \alpha = 0.05, V_{t_0} = 100, \rho = 0.9 \) and \( \gamma = 0.01 \). This is the incomplete market analogue of the previous case. As expected, we have that \( V^* < a_0 \), leading to a smaller fee \( c \) charged by the bank.

Next, in Figure 2, we illustrate the dependence of the loan fee upon the other model parameters. In particular, each curve on the top left plot represents \( c \) as a function of \( \gamma \) for a particular value of the correlation \( \rho \). Similarly, each curve on the top right

![Figure 2. Dependence on model parameters for infinite maturity.](image-url)
plot represents the loan fee value $c$ as a function of $\rho$ for a particular value of the risk aversion $\gamma$. Finally, the curve on the bottom plot represents the loan fee value $c$ as a function of the dividend rate $\delta$. When not explicitly shown in the figure, the values of the remaining parameters are $\sigma_2 = 0.15$, $\delta = 0.05$, $r = \alpha = 0.05$, $L = 90$, $V_0 = 100$, $\rho = 0.9$ and $\gamma = 0.01$.

Observe that the figures confirm the dependences established in Proposition 3.3, namely that the loan fee $c$ is decreasing in $\gamma$ and $\delta$ and increasing in $\rho^2$. Moreover, the limits as $\gamma \to 0$ and $\rho \to \pm 1$ coincide with the complete market, risk-neutral value for the fee obtained in Case 3 of Table 1 for a loan amount $L = 90$, namely $c = 1.9041$.

Observe further that in the incomplete market case, the fee increases sharply as $\delta \to 0$, but converges to the value $c = 65.7048 < 90$ as obtained in Case 2 of Table 1 for $L = 90$.

5.2 Finite Maturity

As mentioned in Section 4.1, the numerical procedures in this case are slightly more involved. First, we use finite differences with projected successive over-relaxation (PSOR) to solve the linear free boundary problem (27). This yields a threshold function $V^*(t)$, which we then use to solve Equation (42) subject to the boundary conditions (43), again by finite differences.

To start with, Table 2 shows the loan fee $c$ for different loan amounts $L$, with the following parameter values: $\sigma_2 = 0.4$, $\rho = 0.4$, $\gamma = 0.01$, $\delta = 0.05$, $r = 0.05$, $\alpha = 0.07$, $V_0 = 100$ and $T = 5$ (in years). Observe that we do not need to restrict ourselves to the case $r = \alpha$ as we did before, since the time-homogeneity property is not used in the finite-maturity case.

Remark 5.1. We used $\rho \geq 0$ throughout all examples, as most stocks are positively correlated with the market index, although this is not necessary for the results to hold. In view of (36), this implies a ‘negative’ excess hedge due to the presence of the option to repay the loan. In other words, the client will partially hedge the option by shorting the index and deposit the proceeds in a bank account with rate $r$. In this context, it is justifiable to use $r < \alpha$ as in some of our examples. On the other hand, when $\rho < 0$, the excess hedge due to the repayment option requires borrowing money from the bank account at a market rate $r$. In this context, the client will seek to enter the stock loan only when $\alpha < r$. In fact, offering the stock as a collateral in order to obtain a loan at below market rates can be viewed as one of the motivations for the whole transaction.

Next, in Figure 3, we illustrate in detail the dependence upon the model parameters analysed in Propositions 4.1 and 4.2. We use $T = 5$, $L = 80$, $\sigma_2 = 0.4$, $r = 0.05$ $\alpha = 0.07$, $\delta = 0.05$, and $\rho = 0.4$ unless otherwise specified. Each curve on the left side

Table 2. Loan fee $c$ for different loan amounts $L$ (finite maturity).
Figure 3. Dependence on model parameters for finite maturity.
represents an optimal exercise boundary \( V^*(t) \) for \( V_0 = 100 \), whereas each curve on
the right side represents the loan fee \( c \) as a function of \( V_0 \), for the particular set of
parameter values described below:

1. For the first row, we use \( \gamma = 0.01, 0.05, 0.08 \) and find that both the optimal exer-
cise boundary and the loan fee decrease as risk aversion increases, in agreement
with item 1 of Proposition 4.1.

2. For the second row, we use \( \delta = 0.05, 0.1, 0.15 \) and find that both the optimal
exercise boundary and the loan fee decrease as the dividend rate increases, in
agreement with item 2 of Proposition 4.1.

3. For the third row, we use \( \rho = 0.05, 0.4, 0.9 \) and find that both the optimal exercise
boundary and the loan fee increase as correlation increases, in agreement with
item 3 of Proposition 4.1.

4. For the last row, we use \( \alpha = r = 0.05 \) and find that the optimal exercise boundary
is strictly decreasing with respect to time to maturity \( (T - t) \), in agreement with
Proposition 4.2.

6. Concluding Remarks

In this paper, we have extended the analysis of Xia and Zhou (2007) for stock loans
in incomplete markets. This allows us to consider the realistic situation when the
borrower faces trading restrictions and cannot use replication arguments to find the
unique arbitrage-free value for the repayment option embedded in such loans. We
showed how an explicit expression for the loan fee can still be found in the infinite-
horizon case, provided the loan interest rate is set to be equal to the risk-free rate. In
the finite-horizon case, we characterize the loan fee in terms of a free-boundary prob-
lem and show how to calculate it numerically. In both cases, we analysed how the loan
fee depends on the underlying model parameters.

Based on the dependence on correlation and risk-aversion, we find that the
complete–market, risk-neutral valuation of a stock loan provides an upper bound for
the fee to be charged by the bank. This shows that by following our model a bank can
quantify the effects of the restrictions faced by the client, thereby charging a smaller
fee for the loan, presumably increasing its competitiveness.

Acknowledgements

We are grateful for valuable comments by S. Shreve, V. Henderson, D. Kramkov,
M. Monoyios and the participants at the Nomura Seminar Series, Oxford (October
2010), and the CCF Seminars, Carnegie Mellon University (April 2011), where
this work was presented. We also acknowledge helpful suggestions by an anony-
mous referee. This work was completed while the first author was visiting Université
d’Evry with financial support by Chaire Risque de Crédit of the Fédération Bancaire
Française.
