Sensitivity analysis of an integrated climate-economic model*

2 3

1

Benjamin M. Bolker † , Matheus R. Grasselli ‡ , and Emma Holmes $^\$$

Abstract. We conduct a sensitivity analysis of a new type of integrated climate-economic model recently proposed 4 5in the literature, where the core economic component is based on the Goodwin-Keen dynamics instead of 6 a neoclassical growth model. Because these models can exhibit much richer behaviour, including multiple 7 equilibria, runaway trajectories and unbounded oscillations, it is crucial to determine their sensitivity to 8 changes in underlying parameters. We focus on four economic parameters (markup rate, speed of price 9 adjustments, coefficient of money illusion, growth rate of productivity) and two climate parameters (size of 10 upper ocean reservoir, equilibrium climate sensitivity) and show how their relative effects on the outcomes 11 of the model can be quantified by methods that can be applied to an arbitrary number of parameters.

12 Key words. Climate change, integrated assessment models, stock-flow consistent models, ecological economics

13 **AMS subject classifications.** 91B55, 91B76, 34C60

14 1. Introduction. Climate change is recognized as one of the largest risks facing the global financial system. Losses due to extreme weather events alone have risen tenfold in the past 40 15years, with a ten-year average now over \$200 billion per year. Even the transition to a low-16 carbon economy poses challenging risks, if only because of the size of the dislocation from carbon-17 intensive portfolios, with total pledged divestment approaching \$15 trillion worldwide. Conversely, 18 19 the needed investment in green technology, mitigation, and infrastructure is at least an order of magnitude larger than current investment flows, thus presenting a growth opportunity for innovative 20 green finance initiatives¹. To adequately address these risks, financial mathematicians need to 2122 use and develop models that integrate economic and climate dynamics in a coherent framework. Mainstream models such as the Dynamic Integrated Climate-Economic (DICE) model [12] and its 23 variants make a poor foundation; not only do they generally omit a banking or financial sector, 24they are also methodologically incompatible with the most salient features of climate science, such 25as nonlinear feedback mechanisms and tipping points [10]. A better alternative consists of stock-26 flow consistent models, in which both the economy and the climate are modelled as a system of 27nonlinear differential equations describing slowly adjusting, out-of-equilibrium quantities [2]. Such 28 models do not assume an equilibrium path with a growing economy a priori. The dynamics of key 2930 economic variables can exhibit runaways, unbounded oscillations and convergence to undesirable equilibria, similar to the behaviour of climate variables in some regimes. 31

On the other hand, the output dynamics of these models can be very sensitive with respect to parameter values. In particular, due to the possibility of multiple equilibria, small changes in parameters or initial values can lead to completely different long-term values for key economic

variables. A preliminary sensitivity analysis of the model in [2] was conducted in [3] in order to investigate the effect of uncertainty in productivity growth, equilibrium temperature sensitivity and a carbon absorption parameter. The purpose of this paper is to extend this analysis in several significant ways.

We start by considering the sensitivity of the model with respect to three additional economic parameters: the speed of price adjustment to fluctuations, the markup rate over labour costs used by firms, and the degree of money illusion in wage bargaining. We establish that the sensitivity with respect to the markup rate is particularly important, because the model converges to two very different equilibria as this parameter varies within the range of empirically observed values.

Based on this observation, we conduct a more detailed analysis to quantify the influence of 44 different parameters on the likelihood of the model converging to an interior equilibrium or one ex-45 hibiting explosive behaviour. Specifically, we perform a logistic regression against the several model 46 parameters, with the categorical response variable describing whether the long-term employment 47rate remains above a given threshold. In this way, we are able to confirm that the markup rate 48 has the largest influence on whether the model converges to an equilibrium with low or high em-49ployment in the long run, and that this effect persists when a full feedback from climate change, 50 in terms of both damages and policy responses, is taken into account. 51

52Finally, whereas [3] reports the distribution of some key output variables, such as temperature anomaly and private debt ratio, when parameter values are drawn from their own distributions, 53it did not describe which parameters contributed the most to the variation in the output. To 54address this, we use the technique adopted in [1] and compute the partial rank correlation of each parameter under consideration with the employment in year 2100, conditional on it being above 56 a threshold (that is to say, conditional on a 'good' equilibrium). Apart from establishing which 57 parameters are positively or negatively correlated with the employment rate, our results indicate 58that the magnitude of the effect of uncertainty in economic parameters on the model outputs is 5960 comparable with that of uncertainty in climate parameters.

61 **2. The Model.** We describe the core economic model without climate change first, followed by 62 the full model with climate damages and policy responses. In what follows, constant parameters 63 are denoted with a bar, whereas a dot denotes a time derivative.

2.1. The Economy. We adopt the formulation presented in [7], based on the original model 64 proposed in [9], with the necessary modifications to make the model compatible with [2] and [3]. 65 The model makes three key sets of assumptions. The first concerns the relation of output with 66 capital and labour in the economy. We assume that real (i.e inflation adjusted) output is given by 67 $Y = \frac{K}{\bar{\nu}}$, where $\bar{\nu}$ is a constant capital-to-output ratio and K is the real capital stock, which evolves 68 according to $\dot{K} = I - \bar{\delta}K$. Here I denotes real investment by firms and $\bar{\delta}$ is a constant depreciation 69 rate. From real output Y, we can obtain the number of employed workers $L = \frac{Y}{a}$, where a denotes 70 the productivity per worker. Denoting the total workforce by N, it follows that the employment 71rate is given by $\lambda = \frac{L}{N} = \frac{Y}{aN}$. 72

The second set of assumptions has to do with the behaviour of firms. Denote nominal profits by $\Pi = pY - wL - \bar{r}D$, where pY is total sales revenue of real output Y at a price level p, w is the average nominal wage rate per worker, and \bar{r} denotes an average constant rate of interest paid on net debt D. The model assumes that real investment by firms is given by $I = \kappa(\pi)Y$ for a function 77 $\kappa(\cdot)$ of the profit share of nominal output

78 (2.1)
$$\pi = \frac{\Pi}{pY} = 1 - \omega - \bar{r}d ,$$

where we have introduced the wage share $\omega = \frac{wL}{pY}$ and the debt-to-output ratio $d = \frac{D}{pY}$. In the absence of any other source of financing, firms have to fund this investment either by using profits or borrowing from banks, from which it follows that the change in net debt of firms is given by $\dot{D} = pI - \Pi + \Delta(\pi)pY$, where the last term denotes dividends paid to shareholders².

The final set of assumptions corresponds to the determination of wages and prices. We assume that the wage rate changes according to $\frac{\dot{w}}{w} = \Phi(\lambda) + \bar{\gamma}i(\omega)$, where $\Phi(\cdot)$, known as the Phillips curve, represents the bargaining power of workers as a function of the employment rate; $\bar{\gamma} \ge 0$ is a coefficient measuring the degree of money illusion (with no illusion corresponding to $\bar{\gamma} = 1$); and $i(\omega)$ corresponds to the inflation rate, which is assumed to be of the form³

88 (2.2)
$$i(\omega) = \frac{\dot{p}}{p} = \bar{\eta}(\bar{\xi}\omega - 1) ,$$

for an adjustment parameter $\bar{\eta} > 0$ and a markup factor $\bar{\xi} \ge 1$.

Finally, we make two additional assumptions that can be relaxed without altering the model in any significant way, namely that labour productivity a grows exponentially at a constant rate $\bar{\alpha}$ and that the workforce N follows the sigmoid function expressed below in (2.3d). With the assumptions and definitions in place so far, the economy can be described by the following fourdimensional system⁴ of coupled nonlinear differential equations for the state variables (λ, ω, d, N) : 95

96 (2.3a)
$$\frac{\dot{\lambda}}{\lambda} = \frac{\kappa(\pi)}{\bar{\nu}} - \bar{\delta} - \bar{\alpha} - \bar{\delta}_N \left(1 - \frac{N}{\bar{N}_{\text{max}}}\right)$$

97 (2.3b)
$$\frac{\dot{\omega}}{\omega} = \Phi(\lambda) - \bar{\alpha} - (1 - \bar{\gamma})i(\omega)$$

98 (2.3c)
$$\frac{d}{d} = \frac{\kappa(\pi) - \pi + \Delta(\pi)}{d} - \left[i(\omega) + \frac{\kappa(\pi)}{\bar{\nu}} - \bar{\delta}\right]$$

99 (2.3d)
$$\frac{N}{N} = \bar{\delta}_N \left(1 - \frac{N}{\bar{N}_{\text{max}}} \right)$$

where π is defined in (2.1) and $\kappa(\cdot)$, $\Phi(\cdot)$ and $\Delta(\cdot)$ are functions that need to be calibrated. For concreteness, we use a linear function for the Phillips curve⁵ and truncated linear functions for the

103 investment and dividends, with parameters specified in Table 1.

 $^{^{2}}$ The original Keen model in [9] does not use dividends, but [2] found necessary to add this term to the model in order to improve the empirical estimates.

³The inflation function used in [2] includes the cost of capital and carbon taxes, in addition to labour, as a cost of production for firms. In [3], this is dropped in favour of the simpler inflation dynamics adopted here. Accordingly, the parameters $(\bar{\eta}, \bar{\xi})$ changed from (0.5, 1.3) in [2] to (0.192, 1.875) in [3]. Both [2] and [3] assume that $\bar{\gamma} = 0$.

⁴In the original model in [9], the growth rate of N is assumed to be a constant β , so that the relevant dynamics reduces to a three-dimensional system with state variables (λ, ω, d) .

⁵For comparison, the parameter values for the Phillips curve were chosen to match those in [3], which were estimated under the assumption that $\bar{\gamma} = 0$. These values would be different if $\bar{\gamma}$ were also estimated from data.

A full analysis of the equilibria for (2.3) is presented in [7] and summarized here. The interior equilibrium, corresponding to a desirable economic situation of nonzero wages and employment, is given by

107 (2.4)
$$(\lambda^*, \omega^*, d^*, N^*) = \left(\Phi^{-1} \big(\bar{\alpha} + (1 - \bar{\gamma}) i(\omega^*) \big), 1 - \pi^* - r d^*, \frac{\kappa(\pi^*) - \pi^* + \Delta(\pi^*)}{\bar{\alpha} + i(\omega^*)}, \bar{N}_{\max} \right),$$

where $\pi^* = \kappa^{-1} [\bar{\nu}(\bar{\alpha} + \bar{\delta})]$. As we can see, substituting the expression for d^* into the expression for 108 ω^* leads to a quadratic equation, from which one can deduce conditions for the existence of at least 109 110 one strictly positive solution (and sometimes two). There are three other possible equilibria for (2.3), all of which correspond to undesirable economic outcomes. The first corresponds to the state 111 variables (λ, ω, d) converging to $(0, 0, \infty)$, namely vanishing wage share and employment rate and an 112explosive debt ratio, as first identified in [5]. The second and third represent equilibrium outcomes 113where the employment rate is zero but the wage share is positive and given by $\omega^{**} = \frac{1}{\xi} + \frac{\Phi(0) - \bar{\alpha}}{\xi \bar{\eta}(1-\bar{\gamma})}$ 114in which case the equilibrium debt share can be either finite or infinite. 115

116 **2.2. The Climate.** The climate part of the model follows [2], which uses a continuous-time 117 version of the DICE model [12]. It begins by specifying the amount of carbon emissions associated 118 with a level Y^0 of industrial production as $E_{ind} = \sigma(1-n)Y^0$, where σ is the carbon intensity of 119 the economy and n is an emissions reduction rate. Regardless of the decisions of firms, we assume 120 that technological progress gradually leads the carbon intensity σ to decrease in time with a rate 121 $g_{\sigma} < 0$, which in turn approaches zero at a constant rate $\bar{\delta}_{g_{\sigma}} < 0$.

To accelerate the transition to an emission-free economy, firms can choose a reduction rate n, 122for which they have to pay abatement costs per unit of production assumed to be of the form 123 $A = \frac{\sigma p_{BS} n^{\bar{\theta}}}{\bar{\theta}}$, where the parameter $\bar{\theta} > 0$ controls the convexity of the cost and p_{BS} is the (inflation 124 adjusted) price of a backstop technology, which we assume to decrease exponentially at a constant 125rate $\bar{\delta}_{p_{BS}}$. The incentive to pay this abatement cost comes from the fact that firms are assumed to 126face a carbon tax of the form $T^C = p_C E_{ind}$, where p_C is the (inflation adjusted) carbon price⁶. On the other hand, firms also receive a subsidy $S^C = \bar{s}_A A Y^0$ equal to a fraction $0 \leq \bar{s}_A < 1$ of their 127 128 abatement costs. Accordingly, the emission reduction rate that minimizes the sum of carbon tax 129130 and abatement cost is given by

131 (2.5)
$$n = \min\left\{ \left(\frac{p_C}{(1-\bar{s}_A)p_{BS}}\right)^{\frac{1}{\theta-1}}, 1 \right\}.$$

In addition to industrial emissions, the model assumes that there are land-use emissions E_{land} that decrease at a constant rate $\bar{\delta}_{E_{land}} < 0$, so that total emissions are given by $E_T = E_{land} + E_{ind}$. These emissions change the average concentrations of carbon dioxide according to the following three-layer model for the atmosphere, the upper ocean and biosphere, and the lower ocean:

136 (2.6)
$$\begin{pmatrix} \dot{CO}_{2}^{AT} \\ \dot{CO}_{2}^{UP} \\ \dot{CO}_{2}^{LO} \end{pmatrix} = \begin{pmatrix} E_{T} \\ 0 \\ 0 \end{pmatrix} + \begin{pmatrix} -\bar{\phi}_{12} & \bar{\phi}_{12}\bar{C}_{UP}^{AT} & 0 \\ \bar{\phi}_{12} & -\bar{\phi}_{12}\bar{C}_{UP}^{AT} - \bar{\phi}_{23} & \bar{\phi}_{23}\bar{C}_{LO}^{UP} \\ 0 & \bar{\phi}_{23} & -\bar{\phi}_{23}\bar{C}_{LO}^{UP} \end{pmatrix} \begin{pmatrix} CO_{2}^{AT} \\ CO_{2}^{UP} \\ CO_{2}^{LO} \end{pmatrix},$$

⁶For direct comparison with [2] and [3], we assume that the carbon price follows the upper bound of the Stern-Stiglitz corridor, namely reaching 80/tC by 2020 and 100/tC by 2030 in 2005 USD units.

where $\bar{C}_{j}^{i} = \frac{\bar{C}^{i}}{\bar{C}^{j}}$ for $i, j = \{AT, UP, LO\}$ are ratios of pre-industrial concentrations $\bar{C}^{AT}, \bar{C}^{UP}, \bar{C}^{LO}$ and $\bar{\phi}_{12}, \bar{\phi}_{23}$ are transfer parameters. In turn, an increase in atmospheric CO₂ concentration 137138 leads to an increase in the Earth's radiative forcing, namely the influx of solar energy that is not 139140 radiated back into space. Specifically, the model assumes that the increase in radiative forcing F_{ind} caused by industrial emissions is a linear function of the logarithm of the ratio of CO_2^{AT} to 141 its preindustrial level. The planet's total increase in radiative forcing from preindustrial levels is 142then given by $F = F_{ind} + F_{exo}$, where F_{exo} is an exogenous increasing function that approaches 143a constant. Finally, the radiative forcing affects the interplay between the temperature anomaly 144(compared to pre-industrial levels) T for the atmosphere and upper ocean and the corresponding 145temperature anomaly T^{LO} for the lower ocean according to the dynamics 146

147 (2.7a)
$$\vec{c}\dot{T} = F - \frac{F_{dbl}}{\bar{S}}T - \bar{h}(T - T^{LO})$$

148 (2.7b)
$$\bar{c}^{LO}\dot{T}^{LO} = \bar{h}(T - T^{LO}),$$

where \bar{F}_{dbl} is a parameter that represents the increase in radiative forcing caused by doubling of pre-industrial atmospheric CO₂ concentration, \bar{c} and \bar{c}^{LO} are the heat capacities of each layer, and \bar{h} is a parameter representing the heat exchange between layers. It follows from (2.7a)-(2.7b) that the equilibrium climate sensitivity (ECS) – defined as the equilibrium temperature anomaly resulting from a doubling of pre-industrial atmospheric CO₂ concentration – is given by the parameter \bar{S} .

To summarize, in the absence of any further feedback to the economy, the climate part of the model can be viewed as a component that takes production Y^0 as an input and returns the average increase in global temperature T as an output through the following chain of causal relationships explained above: $Y^0 \to E_{ind} \to E_T \to CO_2^{AT} \to F_{ind} \to F \to T$.

2.3. Coupling. The economy and the climate are coupled in a unified model as follows. First, as mentioned in the previous section, for a given level of production $Y^0 = \frac{K}{\bar{\nu}}$, firms incur abatement costs AY^0 in order to achieve an emissions reduction rate n. These costs are subtracted directly from production, so that only $(1 - A)Y^0$ is available as output for sale. Next, because of climate change, a fraction **D** of this output is assumed to be irreparably damaged. This fraction is assumed to be a function of temperature anomaly T:

165 (2.8)
$$\mathbf{D} = 1 - \frac{1}{1 + \bar{\zeta}_1 T + \bar{\zeta}_2 T^2 + \bar{\zeta}_3 T^{\bar{\zeta}_4}}$$

where $\bar{\zeta}_1$, $\bar{\zeta}_2$, $\bar{\zeta}_3$, $\bar{\zeta}_4$ are given parameters⁷. Consequently, the output actually sold by firms is given by $Y = (1 - \mathbf{D})(1 - A)Y^0$. Accordingly, profits for firms need to be modified as

168 (2.9)
$$\Pi = (1 - \mathbf{D})(1 - A)pY^0 - wL - \bar{r}D + p(S^C - T^C) ,$$

where S^C and T^C are the (real) government subsidy and carbon tax mentioned in the previous section, with the correspondingly redefined profit share $\pi = \frac{\Pi}{nY}$.

In order to avoid taking derivatives of the damage function and abatement costs, it is computationally more convenient to use the extensive variables (K, D, w, p, a, N) as state variables

⁷The desired convexity of such damage curves is contested in the literature: see [4] for critiques of the function used in [12]. Nevertheless, for comparison with [2] and [3] we use the Nordhaus damage function as in [12]. This assumption can be relaxed to allow for varying, and arguably more realistic, levels of damages.

Table 1Model parameters

Symbol	Value	Parameter description
ā	0.02	Productivity growth rate
$\overline{\delta}$	0.04	Depreciation rate of capital
$\bar{\nu}$	2.7	Capital to output ratio
$\bar{\delta}_N$	0.031	Work force growth parameter
\bar{N}_{max}	7.065	Work force equilibrium value
$\overline{\Phi}_0$	-0.292	Phillips curve y-intercept
$\overline{\Phi}_1$	0.469	Phillips curve slope
$\bar{\kappa}_0$	0.0318	Investment function y-intercept
$\bar{\kappa}_1$	0.575	Investment function slope
$\bar{\kappa}_{min}$	0	Investment function minimum
$\bar{\kappa}_{max}$	0.3	Investment function maximum
$\bar{\Delta}_0$	-0.078	Dividend function y-intercept
$\bar{\Delta}_1$	0.553	Dividend function slope
$\bar{\Delta}_{min}$	0	Dividend function minimum
$\bar{\Delta}_{max}$	0.3	Dividend function maximum
\bar{r}	0.02	Long term interest rate
$\bar{\eta}$	0.192	Inflation relaxation parameter
$ar{\eta}$ $ar{\xi}$ $ar{\gamma}$ $ar{C}^{AT}$	1.875	Price markup
$\bar{\gamma}$	0.9	Effect of inflation on wages
\bar{C}^{AT}	588	Preindustrial concentration of CO_2 in the atmosphere
\bar{C}^{UP}	360	Preindustrial concentration of CO_2 in the upper ocean
\bar{C}^{LO}	1720	Preindustrial concentration of CO_2 in the lower ocean
$\bar{\phi}_{12}$	0.024	Transfer coefficient for carbon from AT to UP
$\overline{\phi}_{23}$	0.001	Transfer coefficient for carbon from UP to LO
$\bar{\delta}_{g\sigma}$	-0.001	Variation rate of the growth of emission intensity
$\bar{\delta}_{E_{land}}$	-0.022	Growth rate of land use change CO_2 -equivalent emissions
$\bar{\delta}_{pBS}$	-0.005	Growth rate of the price of backstop technology
\bar{F}_{dbl}	3.681	Change in radiative forcing from a doubling of preindustrial CO ₂
\overline{F}_{dbl} $\overline{F}_{ero}^{start}$	0.5	Starting value of exogenous radiative forcing
\bar{F}_{exo}^{end} \bar{F}_{exo}^{end}	1	Ending value of exogenous radiative forcing
\bar{T}_{preind}	13.74	Preindustrial temperature, in degrees Celsius
Ē	10.20	Heat capacity of atmosphere and upper ocean layer
\bar{c}^{LO}	3.52	Heat capacity of the lower ocean layer
	0.0176	Heat exchange coefficient between temperature layers
\bar{S}	3.1	Equilibrium climate sensitivity, in degrees Celsius
$\bar{\zeta}_1$	0	Damage function parameter
$\bar{\zeta}_2$	0.00236	Damage function parameter
$\bar{\zeta}_3$	0	Damage function parameter
$\bar{\zeta}_4$	0	Damage function parameter
$\bar{\theta}$	2.6	Abatement cost function parameter
$ \bar{\bar{h}} \bar{\bar{S}} \bar{\bar{\zeta}}_1 \bar{\bar{\zeta}}_2 \bar{\bar{\zeta}}_3 \bar{\bar{\zeta}}_4 \bar{\bar{\theta}} \bar{\bar{s}}_A $	0.5	Fraction of abatement costs subsidized by government
$\bar{\delta}_{C,1}$	25.69	Linear growth rate of the carbon price up to 2020
$\bar{\delta}_{C,2}$	2.53	Linear growth rate of the carbon price from 2020 onwards

173 for the economic model, instead of the intensive-form system in term of the ratios (λ, ω, d) , 174 although both these formulations can be shown to be equivalent. Adding the state variables 175 $(\sigma, g_{\sigma}, E_{land}, CO_2^{AT}, CO_2^{UP}, CO_2^{LO}, T, T^{LO}, p_{BS}, p_C)$ from the climate component described in the 176 previous section leads to a 16-dimensional combined economic-climate model.

A limited analysis of the equilibria for the full model is provided in [2]. Assuming no inflation, 177they show that, once the temperature level has reached equilibrium, the 'good' equilibrium – where 178the economy grows at a constant rate, employment and wages are positive, and the debt ratio is 179finite - exists. This equilibrium is similar to (2.4). Further scenario analysis is done numerically 180 in [2] and a sensitivity analysis with respect to the parameters $\bar{\alpha}$ (growth rate of output), \bar{S} 181 (equilibrium climate sensitivity), and \bar{C}^{UP} (size of the intermediate climate reservoir) is provided 182in [3]. In the next section, we present a more complete sensitivity analysis taking into account some 183184 key economic parameters.

3. Sensitivity Analysis. We investigate the sensitivity of the economic model without climate change first, followed by an analysis of the full model. Numerical results were obtained by solving the models in R using the package deSolve [15] with the lsoda integration method⁸.

3.1. Sensitivity of the Economic Model. As pointed out in [7], depending on the choice of parameters, the pricing dynamics (2.2) can significantly alter the outcome of the underlying Keen model, because of both the possibility of deflation and the introduction of new undesirable equilibrium points.

To explore the parameter space, the model was run up to year 2300 as in [2], with 20 output time-steps per year, for inflation parameters in the ranges shown in Figure 1, which were chosen to include the available empirical estimates. Points were selected from the parameter space using Sobol sequences [14] implemented by the R package qrng [8].

The outcome of each individual model run was categorized into three possibilities, based on the 196ending values of the simulation: 'good' if $0.4 \le \lambda \le 1$, $0.4 \le \omega \le 1$, and $d \le 2.7 = \bar{\nu}$, corresponding 197 to an economy with employment and wages bounded away from zero and debt less than the total 198 capital stock, that is to say, the 'convergence set' specified in footnote 30 of [2]; 'outside bounds' 199 if one of λ or ω ended above 1; or 'bad' otherwise. The bad outcomes include all of the equilibria 200 corresponding to the vanishing employment rates mentioned above, as well as the interior equilibria 201 202 with low but positive wage shares, which are associated with low inflation (and sometimes even 203 deflation) through (2.2), and consequently low employment rates through (2.4).

The top graphs in Figure 1 show the results for the economic model alone, starting with two 204sets of initial conditions: (a) favourable initial conditions, meaning that initially the employment 205rate and wage share in the economy are high and the debt share is low, and (b) unfavourable initial 206207 conditions, with lower initial wages and employment and higher initial debt, matching the initial conditions used in [2]. As we can see in the figure, the key parameter affecting the model outcome is 208 the markup rate $\bar{\xi}$. There are slightly more bad outcomes for low values of the parameter $\bar{\gamma}$ (higher 209210 degree of money illusion) or a high relaxation parameter $\bar{\eta}$ (faster price adjustments), but the effects are not pronounced. We see that some choices of pricing parameters create high oscillation in the 211model or otherwise keep the model from converging to an economically meaningful equilibria by 2122300, as represented by the purple area in the graphs. 213

An alternative way to explore this result is to look at how changing the markup rate ξ changes 214 215the basin of attraction to the 'good' equilibrium. The graphs (a) to (c) in Figure 2 show the results of running the economic model for a range of initial conditions corresponding to the 'initial set' 216specified in footnote 29 of [2]. The other pricing parameters are fixed at $\bar{\gamma} = 0.9$ and $\bar{\eta} = 0.4$ and we 217use the same categorized outcomes as in Figure 1. We can see that increasing the markup rate from 218 $\xi = 1.3$ (as used in [2] for an inflation specification that included the cost of capital) to $\xi = 1.875$ 219220 (as used in [3] for the same inflation specification adopted here) increases the basin of attraction to the good equilibrium (2.4), whereas reducing the markup rate to 1.18 has the opposite effect. 221

For a more detailed analysis, we follow [3] and perform simulations of the model with parameters drawn from probability distributions fitted to the empirical estimates. Namely, the productivity growth rate $\bar{\alpha}$ is drawn from a normal distribution with mean 2.06 and standard deviation 1.12 as in [3], whereas for the inflation parameters we use the estimates in [6, Online Appendix] and assume that: (1) $\bar{\eta}$ is drawn from a normal distribution with mean 0.4 and standard deviation of

⁸The code used in this paper is available at https://github.com/emmaaholmes/econ-climate-sensitivity and is an extension of the code provided by the authors of [2] and [3]. Any remaining errors are ours.

(c) $(\lambda(0), \omega(0), d(0)) = (0.9, 0.9, 0.3)$ (d) $(\lambda(0), \omega(0), d(0)) = (0.675, 0.578, 1.53)$

Figure 1. Outcomes of the economic model (top) and the full model (bottom) for a range of inflation parameters and two different sets of initial conditions. A 'good' outcome (green) means the final result satisfies $(\lambda, \omega, d) \in$ $[0.4, 1]^2 \times (-\infty, 2.7]$, 'outside bounds' (purple) means that either $\lambda > 1$ or $\omega > 1$, and all other outcomes are classified as 'bad' (light orange). Remaining initial conditions match those in [2]. Namely, using \$ for 2010 USD and tC for ton of CO_2 -equivalent: K(0) = \$161.3 trillion, N(0) = 4.83 billion workers, p(0) = 1 (normalization constant), $\sigma(0) = 0.6187$ tC/\$1000, $g_{\sigma}(0) = -0.0105$ (year)⁻¹, $E_{land}(0) = 2.6$ GtC/year, $p_{BS}(0) = $547.22/t$ C, $p_C(0) = $1/t$ C, $CO_2^{AT}(0) = 851$ GtC, $CO_2^{UP}(0) = 460$ GtC, $CO_2^O(0) = 1740$ GtC, $T(0) = 0.85^{\circ}$ C, $T^O(0) = 0.0068^{\circ}$ C.

227 0.12; (2) $\bar{\xi}$ is drawn from a generalized Gamma distribution with shape parameter s = 3.0894, 228 scale parameter m = 0.7154, and family parameter f = 0.9959, shifted right one unit; and (3) $\bar{\gamma}$ is 229 drawn from a generalized Gamma distribution with shape parameter s = 6.2327, scale parameter 230 m = 0.0033, and family parameter f = 0.3158, reflected in the y-axis and shifted right one unit.

The simulations were conducted by sampling 1000 times from the given probability distributions for the inflation and growth parameters and running the model for each choice using the same initial conditions in 2016, namely $(\lambda(0), \omega(0), d(0)) = (0.675, 0.578, 1.53)$ as specified in [2]. We then sorted the outcome of the model into two categories — good and bad — depending on whether or not

Figure 2. Outcomes of the economic model (top) and the full model (bottom) for a range of initial conditions and three different values of the markup rate $\bar{\xi}$. Increasing the markup rate increases the numerically-computed basin of attraction to the 'good' equilibrium (green region), confirming the results shown in Figure 1.

the employment rate in 2100 is above 40% and performed a logistic regression of this categorical 235236 outcome with respect to the four parameters, with inputs standardized as described in [13] using the R function scale. Next, to quantify how the uncertainty in an input variable affects the output, 237238 we followed [1] and computed the partial rank correlation coefficient (PRCC) associated with each parameter, using the employment rate for good outcomes as the output variable. The results are 239shown in the top panels of Figure 3 (green dots) and indicate that the markup rate has a strong 240241 effect on the outcome, confirming the conclusions obtained from the top part of Figure 1. Moreover, conditioned on converging to a good outcome, the markup rate $\bar{\xi}$ and the money illusion parameter 242 $\bar{\gamma}$ have similar effects on the outcome, but in opposite directions. The relaxation parameter $\bar{\eta}$ and 243 244 the productivity growth rate $\bar{\alpha}$ have slightly smaller effects.

3.2. Sensitivity of the Full Model. We now repeat the analysis using the full 16-dimensional integrated climate-economic model. As a preliminary result, the graphs (c) and (d) in Figure 1 and (d) to (f) in Figure 2 show the outcomes of the full model using the same sets of initial conditions for (λ, ω, d) , parameter values $(\bar{\eta}, \bar{\xi}, \bar{\gamma})$, and classification criterion as before, whereas for the remaining initial conditions we use the values specified in [2]. We observe broadly similar results as for the economic model, indicating that the inflation parameters, in particular the markup factor $\bar{\xi}$, still play an important role in determining the long-term behaviour of the outcomes in the full model.

For a more detailed sensitivity analysis, we again draw model parameters from probability

253 distributions matching available empirical estimates. In addition to the inflation and growth pa-254 rameters, we follow [3] and consider uncertainty in two climate-related parameters: the equilibrium

climate sensitivity \bar{S} and the size \bar{C}^{UP} of the intermediate climate reservoir. Specifically, \bar{S} is drawn

256 from a log-normal distribution with log-mean 1.107 and log-standard deviation 0.264, and C^{UP} is

drawn from a log-normal distribution with log-mean 5.886 and log-standard deviation 0.251, which

correspond to the distributions used in [3] to match the estimates provided in [11].

Figure 3. Logistic regression coefficients and partial rank correlation coefficients for the markup rate $\bar{\xi}$, the relaxation parameter $\bar{\eta}$, the money illusion parameter $\bar{\gamma}$, the size of the intermediate climate reservoir \bar{C}^{UP} and the equilibrium climate sensitivity \bar{S} .

As before, the parameters are sampled from their distributions 1000 times and the model is run with the same initial conditions taken from [2]. The same procedure is performed to calculate logistic regression coefficients, where the outcome variable is whether or not the employment rate in 2100 is above 40%, and partial rank correlation coefficients, where the outcome variable is the employment rate in 2100, conditional on being above 40%. The analysis is performed twice, first with the full model but without climate damages and policy, and then again with climate damages, carbon tax and a government subsidy.

The results are shown in the remaining panels of Figure 3. When neither damages nor government policy are taken into account (blue dots, middle panels), the logistic regression coefficients again indicate that the markup rate $\bar{\xi}$ has the largest effect, with the labour productivity growth rate $\bar{\alpha}$ and the relaxation parameter $\bar{\eta}$ also having effects significantly different from zero. The PRCC values show that, in this case, uncertainty in the pricing parameters has a greater effect on the outcome than uncertainty in the variables examined in [3], which is unsurprising, given that in this example there is no feedback from the climate into the economic model. For the full model with climate damages, a carbon tax policy and government subsidy (red dots, bottom panels), we can see that the climate parameters all have a larger effect, both in determining whether or not the model converges to a good output and in the variability of employment rate in the good outcomes. Interestingly, however, the effects of the inflation parameters are comparable in size to those of the climate ones, meaning that uncertainty in both sets of parameters needs to be taken into account in evaluating the robustness of the model.

Figure 4. Results of a Monte Carlo simulation of the full model with (in red) and without (in blue) climate damages and government policy. The medians and the 95% confidence intervals are shown for all runs, including both 'good' and 'bad' outcomes.

As a final illustration, Figure 4 depicts the trajectories of select state variables of the model. 279Differently from the results presented in Figure 3, this figure shows the values for all runs, instead 280 281 of only those converging to outcomes with employment higher than 40%, as this allows us to obtain estimates for the unconditional distribution of key state variables. For example, we find that, in 282the full model with climate feedback and government policy, the temperature anomaly by 2100 283remains below the 2°C Paris accord target in 23.8% of the runs with a median value 2.37°C, the 284debt-to-output ratio remains below the acceptable value 2.7 in 84.7% of the runs, and both variables 285 remain below these thresholds in 20% of the runs, broadly similar to the results reported in [3]. 286

4. Conclusion. In this paper, sensitivity analysis was conducted on a Keen-based model of the climate and the economy. The model is similar to that of [2], but with the pricing dynamics of [7] and slight simplifications to the damage curve and path of the carbon price. The parameter space was explored numerically using Sobol sampling and Monte Carlo methods. We show that convergence of the model to an interior equilibrium is sensitive to small changes in some key parameters: the inflation markup rate $\bar{\xi}$, the labour productivity growth rate $\bar{\alpha}$, and the speed of price adjustment $\bar{\eta}$. Furthermore, conditional on convergence, we show that uncertainty on economic and climate parameters have quantitatively comparable effects on the outcome of the model.

These results indicate that sensitivity analyses of integrated climate-economic models need 295296 to take into account uncertainties in all relevant parameters, as they can have significant effects on the conclusions drawn from the model. Accordingly, a future avenue for research would be 297 to estimate these parameter values from existing economic data, as was done in [6], but for this 298specific version of the Keen model with climate and some of its extensions. Such a study would 299allow for stronger conclusions about the effectiveness of differing government climate policies, such 300 301 as carbon taxes, green technology subsidies, as well as traditional monetary or fiscal policies in stabilizing the inherently complex interactions between the climate and the economy. 302

Acknowledgments. We are grateful for stimulating discussions with Florent Mc Isaac, Etienne Espagne, Devrim Yilmaz, Antoine Godin, Gaël Giraud and the participants of the Georgetown Environmental Justice Program Seminar, where this work was presented, and also for the helpful remarks by the anonymous referee and review editor for this paper.
